

Bounds on quantum ordered searching

Peter Høyer^{*}

Jan Neerbek[‡]

Abstract

We prove that any exact quantum algorithm searching an ordered list of N elements requires more than $\frac{1}{\pi}(\ln(N) - 1)$ queries to the list. This improves upon the previously best known lower bound of $\frac{1}{12}\log_2(N) - O(1)$. Our proof is based on a weighted all-pairs inner product argument, and it generalizes to bounded-error quantum algorithms.

The currently best known upper bound for exact searching is roughly $0.526\log_2(N)$. We give an exact quantum algorithm that uses $\log_3(N) + O(1)$ queries, which is roughly $0.631\log_2(N)$. The main principles in our algorithm are an quantum parallel use of the classical binary search algorithm and a method that allows basis states in superpositions to communicate.

1 Introduction

Searching ordered lists is one of the most fundamental and most studied problems in the theory of algorithms. Given an ordered list and some element, the ordered search problem is to find the index of that element. We are interested the quantum black box complexity of searching, which is a quantum analogue of the decision tree complexity.

Formally, the input is a sorted Boolean list of size N and the problem is to find the index of the leftmost 1. We assume that the list is given as a black box, so the only way we can obtain information about the list is via queries. The input to a query is an index and the output is the bit of the list at that index. We assume that not all values of the list are 0 and hence the problem is always well-defined.

The classical query complexity of this problem is, as is well known, exactly $\lceil \log_2(N) \rceil$. Farhi, Goldstone, Gutmann and Sipser [10] have shown that on a quantum computer, we can solve this problem using only roughly $0.526\log_2(N)$ queries. The previously best known lower bound is due to Ambainis [1] who recently proved that $\frac{1}{12}\log_2(N) - O(1)$ queries are required. We improve this lower bound to $\frac{1}{\pi}(\ln(N) - 1)$ which is about $0.221\log_2(N)$. Thus, a speedup by a constant factor somewhere between 1.9 and 4.6 is achievable.

There are at least three reasons why the quantum complexity of the ordered searching problem seems to be of interest. Firstly because of its significance in algorithmics in general. Secondly because the problem possesses some symmetries and periodicities of a

[‡]Department of Computer Science, University of Aarhus, DK-8000 Århus C, Denmark. email: neerbek@daimi.au.dk.

different nature than previously studied problems in quantum algorithmics. Determining symmetries and periodicities seems to be a primary ability of quantum computers and it is not at all clear how far-reaching this skill is. Thirdly because ordered searching represents a non-Boolean non-symmetric function. A (partial) function is said to be symmetric if for each possible Hamming weight, the function is either not defined for any input of that Hamming weight, or it takes the same value on all inputs of that Hamming weight. Searching ordered lists is not such a problem since it is only defined for exactly 1 input of each Hamming weight. Only few non-trivial quantum bounds for non-Boolean non-symmetric functions are known.

We prove our lower bound of $\frac{1}{\pi}(\ln(N) - 1)$ by utilizing what we refer to as a weighted all-pairs inner product argument. We hope that this proof technique, which extends previous work by especially Bennett, Bernstein, Brassard and Vazirani [4] and Ambainis [2], will be of use elsewhere. We first give a description of our proof technique in Section 2, by utilizing which we prove a general lower bound in Section 3. We then apply the technique to ordered searching in Section 4.

In Section 5, we give a new quantum algorithm for ordered searching. Our algorithm is exact and uses $\log_3(N) + O(1)$ queries, which is roughly $0.631 \log_2(N)$. This is better than classically, but not as good as the currently best known algorithm which requires only roughly $0.526 \log_2(N)$ queries [10]. Whereas most quantum algorithms is based on Fourier transform and amplitude amplification, our algorithm can be viewed as a quantum version of the classical (binary search) algorithm. Our main idea is to run several applications of the binary search algorithm in quantum parallel, and let them find the element in teamwork. We let some applications concentrate primarily on some parts of the inputs, meanwhile other applications concentrate primarily on other parts of the input. Depending on where the searched element is, this implies that some applications learn a great deal (about where the element is), whereas others learn only little. We then, as our main trick, use a method for letting the different applications learn from each other, in the sense that the applications that know the most about the input inform the other applications, hereby letting everybody learn a great deal about the input. Letting the different applications work as a team allows us reduce the complexity from $\log_2(N)$ to roughly $\log_3(N)$.

Finally, we conclude in Section 6 with some remarks and open questions.

2 Quantum black box computing

We use the so-called black box model in which the input is given as an oracle and our measure of complexity is the number of queries to the oracle [5, 3]. Fix some positive integer $N > 0$. The input $x = (x_0, \dots, x_{N-1}) \in \{0, 1\}^N$ is given as an oracle, and the only way we can access the bits of the oracle is via queries. A query implements the operator

$$O_x : |z; i\rangle \longmapsto \begin{cases} (-1)^{x_i} |z; i\rangle & \text{if } 0 \leq i < N \\ |z; i\rangle & \text{if } i \geq N. \end{cases} \quad (1)$$

Here i and z are non-negative integers. By a query to oracle x we mean an application of the unitary operator O_x . We sometimes refer to O_x as the oracle. A quantum algorithm A

that uses T queries to an oracle O is a unitary operator of the form

$$A = (UO)^T U. \quad (2)$$

We always apply algorithm A on the initial state $|0\rangle$, and after applying A , we always measure the final state in the computational basis. Thus, a quantum algorithm for oracle quantum computing is defined by specifying a unitary operator U and a number of iterations T . Our model for oracle quantum computing is slightly different from, but equivalent to, the “standard” model used for example in [3]. We favor utilizing this model, since hereby oracle O_x is a diagonal matrix with respect to the computational basis.

Consider the computation of some function $f : \{0, 1\}^N \rightarrow \{0, 1\}^m$. After applying quantum algorithm A on $|0\rangle$, we measure the m rightmost qubits of $A|0\rangle$ and output the outcome w . The success probability p_x of A on input $x \in \{0, 1\}^N$ is defined as the probability that $w = f(x)$. For complete functions $f : \{0, 1\}^N \rightarrow \{0, 1\}^m$, we define the success probability of A as the minimum of p_x over all $x \in \{0, 1\}^N$. For partial functions $f : S \rightarrow \{0, 1\}^m$, where $S \subseteq \{0, 1\}^N$, we take the minimum over S only.

2.1 Distinguishing oracles

There is a key conceptual idea which is used in this paper and which we would like to emphasize, and that is that we are concerned about *distinguishing* oracles rather than *determining* the value of the function f . This is a line of thought that we have learned primarily from Ettinger [8] and Farhi, Goldstone, Gutmann and Sipser [11]. Thus the general question we are interested in is that of distinguishing operators as opposed to distinguishing states or computing functions. We now give our version of such an approach applied to black box computing.

The basic observation is that some oracles are easier to distinguish between than others. Intuitively, it is easier to distinguish between the oracle $x = (0, 0, \dots, 0)$ of all zeros and the oracle $x = (1, 1, \dots, 1)$ of all ones, than it is to distinguish between two oracles of almost the same Hamming weight. One reason for a problem to be hard, is if we want to distinguish between oracles of almost the same Hamming weight. In general, if a problem is hard, it is because that there are some pairs of oracles that are hard to distinguish. Other pairs of oracles might be easy to distinguish, but that may not necessarily lower the complexity of the problem.

For a given problem we therefore want to identify the *pairs of oracles* that are hard to *distinguish*. This idea is applicable when proving lower as well as upper bounds. To capture the hardness of distinguishing each pair of oracles, we introduce a *weight function*

$$\omega : \{0, 1\}^N \times \{0, 1\}^N \rightarrow \mathbb{R}_+ \quad (3)$$

that takes non-negative real values. The harder an oracle x is to distinguish from an oracle y , the more weight we put on the pair (x, y) . The total weight W distributed is the sum of $\omega(x, y)$ over all pairs $(x, y) \in \{0, 1\}^N \times \{0, 1\}^N$. We do not want to put any restrictions on ω in general, though for many applications we probably want ω to be symmetric, normalized and take the value 0 along the diagonal.

The weight function allows us to easily capture any complete as well as partial function. Let $f : S \times S \rightarrow \{0, 1\}^m$ be a function of interest, where $S \subseteq \{0, 1\}^N$. We say that

ω is a weight function for f if whenever $f(x) = f(y)$ then $\omega(x, y) = 0$, and if for every pair $(x, y) \notin S \times S$ we have $\omega(x, y) = 0$. Hereby, we may ignore f and just consider the scenario in which we are given weight function ω .

3 General lower bound

The first general technique for proving lower bounds for quantum computing was introduced by Bennett, Bernstein, Brassard and Vazirani in their influential paper [4]. Their beautiful technique is nicely described in Vazirani's exposition [14]. Our technique is a natural generalization of theirs, but it can also be viewed as a generalization of Ambainis' powerful entanglement lower bound approach recently proposed in [2] (provided one casts his technique using a language similar to the one used in [4] and here).

Here is the basic idea: Consider a quantum algorithm $A = (\text{UO})^T \text{U}$ that we use to distinguish between two oracles $x, y \in \{0, 1\}^N$. Our initial state is $|0\rangle$. After j iterations, our state is $|\psi_x^j\rangle = (\text{UO}_x)^j \text{U}|0\rangle$ if we are given oracle x , and it is $|\psi_y^j\rangle = (\text{UO}_y)^j \text{U}|0\rangle$ if we are given oracle y . Two quantum states are distinguishable with high probability if and only if they are almost orthogonal. If the states $|\psi_x^j\rangle$ and $|\psi_y^j\rangle$ have large overlap, then they cannot be distinguished with high probability, and hence more queries are required. If a query can separate two states $|\psi_x^j\rangle$ and $|\psi_y^j\rangle$ by only a small additional amount, then many queries are required.

We have to choose how to measure the overlap of states among the plentiful studied measures. We pick here the probably most simple possibility: inner products. Two states can be distinguished with certainty if and only if their inner product is zero. Furthermore, two states can be distinguished with high probability if and only if their inner product is of small absolute value.

Lemma 1 *Suppose that we are given one of two states $|\Psi_x\rangle, |\Psi_y\rangle$. There exists some measurement that will correctly determine which of the two states we are given with error probability at most ϵ if and only if $|\langle \Psi_x | \Psi_y \rangle| \leq 2\sqrt{\epsilon(1-\epsilon)}$.*

We are not only interested in distinguishing two particular oracles, but many oracles, and thus we will use an “all-pairs inner product” measure. But as we discussed in the previous section, some oracles are harder to distinguish than others, and this leads us to our final choice: we use an *all-pairs inner product measure weighted by ω* . We now formalize this approach.

Let $A = (\text{UO})^T \text{U}$ be any quantum algorithm. For every oracle $x \in \{0, 1\}^N$ and every integer $j \geq 0$, let

$$|\psi_x^j\rangle = (\text{UO}_x)^j \text{U}|0\rangle \quad (4)$$

denote the state of the computer after applying j iterations using oracle O_x . For every integer $j \geq 0$, let

$$W_j = \sum_{x, y \in \{0, 1\}^N} \omega(x, y) \langle \psi_x^j | \psi_y^j \rangle. \quad (5)$$

denote the weighted all-pairs inner product after j iterations. Initially, the total weight is $W_0 = W$. After T iterations, the total weight is $W_T = \sum_{x, y \in \{0, 1\}^N} \omega(x, y) \langle \psi_x^T | \psi_y^T \rangle$.

If algorithm A is capable of distinguishing with certainty between all pairs of oracles $(x, y) \in \{0, 1\}^N \times \{0, 1\}^N$ of nonzero weight, then $W_T = 0$. Conversely, if $W_T > 0$ then there exists some pair of oracles (x, y) with $\omega(x, y) > 0$ between which algorithm A does not distinguish perfectly.

In summary, initially all inner products are 1 and the initial weight is therefore W , whereas at the end of the computation all inner products are hopefully small and the final weight W_T is therefore small. If the total weight can decrease by at most Δ by each query, we require at least W/Δ queries to perfectly distinguish between all pairs of oracles of nonzero weight.

Theorem 2 *Let $f : S \rightarrow \{0, 1\}^m$ be a given function where $S \subseteq \{0, 1\}^N$, and let ω be a weight function for f . Let $A = (\text{UO})^T \text{U}$ be any quantum algorithm that computes f with error at most $\epsilon \geq 0$ using T queries. Then*

$$T \geq \left(1 - 2\sqrt{\epsilon(1 - \epsilon)}\right) \frac{W}{\Delta} \quad (6)$$

where $W = \sum_{x, y \in \{0, 1\}^N} \omega(x, y)$ denotes the initial weight, and Δ is an upper bound on $|W_j - W_{j+1}|$ for all $0 \leq j < T$.

Proof By definition, $W_0 = W$, and by Lemma 1, $|W_T| \leq 2\sqrt{\epsilon(1 - \epsilon)}W$. Write $W_0 - W_T = \sum_{j=0}^{T-1} (W_j - W_{j+1})$ as a telescoping sum. Then $|W_0 - W_T| \leq \sum_{j=0}^{T-1} |W_j - W_{j+1}| \leq T\Delta$, and the theorem follows. $\square$

Our formulation of Theorem 2 has been heavily inspired by the general formulations used by Ambainis in [2]. In [4], Bennett, Bernstein, Brassard and Vazirani are interested in distinguishing one unique oracle x' from all other oracles. That is, for every pair of oracles $(x, y) \in \{0, 1\}^N \times \{0, 1\}^N$ of interest, we have $x = x'$. Ambainis [2] removes this restriction, and he also allows a non-uniform interest in different oracles by weighting each oracle individually. We are also interested in distinguishing general pairs of oracles, but we discriminate our interest in each pair by weighting each *pair of oracles* via weight function ω . This discrimination is essential in our application to ordered searching.

4 Lower bound on ordered search

Searching ordered lists is a non-Boolean promise problem: the list is promised to be sorted, and the answer is an index, not a bit. Formally, the set S of N possible inputs consists of all $x \in \{0, 1\}^N$ for which $x_0 = 0$ and $x_{i-1} \leq x_i$ for all $1 \leq i < N$. The search function $f : S \rightarrow \{0, 1\}^m$ is defined by $f(x) = \min\{0 \leq i < N \mid x_i = 1\}$, where we identify the result $f(x)$ with its binary encoding as a bit-string of length $m = \lceil \log_2(N) \rceil$.

The classical query complexity of this problem is, as is well known, exactly $\lceil \log_2(N) \rceil$. The best known quantum algorithm for this problem requires roughly $0.526 \log_2(N)$ queries and is due to Farhi, Goldstone, Gutmann and Sipser [10]. The first lower bound of $\sqrt{\log_2(N)} / \log_2 \log_2(N)$ was proved by Buhrman and de Wolf [6] by an ingenious quantum reduction from the OR problem. Farhi, Goldstone, Gutmann and Sipser [9] improved this to $\log_2(N) / 2 \log_2 \log_2(N)$, and Ambainis [1] then recently proved the previous best known lower bound of $\frac{1}{12} \log_2(N) - O(1)$. In [9, 1], they use, as we do here, an inner product argument along the lines of [4].

The first and essential step in our lower bound is to pick a good weight function ω for f . We choose

$$\omega(x, y) = \begin{cases} \frac{1}{f(y)-f(x)} & \text{if } (x, y) \in S \times S \text{ and } f(x) < f(y) \\ 0 & \text{otherwise.} \end{cases} \quad (7)$$

That is, we use the inverse of the Hamming distance of x and y . Intuitively, a weight function that (only) depends on the Hamming distance ought to be a good choice since it can put most weight on pairs of oracles that are almost identical.

The initial weighted all-pairs inner product is

$$W_0 = \sum_{x, y \in \{0,1\}^N} \omega(x, y) = \sum_{i=1}^{N-1} H_i = NH_N - N, \quad (8)$$

where $H_i = \sum_{k=1}^i \frac{1}{k}$ denotes the i th harmonic number. Note that $\ln(N) < H_N < \ln(N) + 1$ for all $N > 1$. Since any query can decrease the weighted all-pairs inner product by at most πN , our main theorem follows by applying Theorem 2.

Lemma 3 *For weight function ω defined by Eq. 7, we have that*

$$|W_j - W_{j+1}| \leq \pi N$$

for all $0 \leq j < T$.

Theorem 4 (Main) *Any quantum algorithm for ordered searching that errs with probability at most $\epsilon \geq 0$ requires at least*

$$\left(1 - 2\sqrt{\epsilon(1-\epsilon)}\right) \frac{1}{\pi} (H_N - 1) \quad (9)$$

queries to the oracle. In particular, any exact quantum algorithm requires more than $\frac{1}{\pi}(\ln(N) - 1)$ queries.

We end this section by given our proof of Lemma 3.

Proof of Lemma 3 For any oracle $x \in \{0,1\}^N$, we will think of x as an infinite bit-string where $x_i = 0$ for all $i \geq N$. Operator O_x defined by Eq. 1 is then given by

$$O_x = \sum_{z \geq 0} \sum_{i \geq 0} (-1)^{x_i} |z; i\rangle \langle z; i|.$$

Let $\mathbf{I}$ denote the identity operator. For every $i \geq 0$, let $P_i = \sum_{z \geq 0} |z; i\rangle \langle z; i|$ denote the projection operator onto the subspace querying the i th oracle bit.

Let $0 \leq j < T$. By definition

$$\begin{aligned} W_j - W_{j+1} &= \sum_{x, y \in \{0,1\}^N} \omega(x, y) \langle \psi_x^j | \psi_y^j \rangle - \sum_{x, y \in \{0,1\}^N} \omega(x, y) \langle \psi_x^{j+1} | \psi_y^{j+1} \rangle \\ &= \sum_{x, y \in \{0,1\}^N} \omega(x, y) \langle \psi_x^j | \mathbf{I} - O_x^{-1} O_y | \psi_y^j \rangle \\ &= 2 \sum_{x, y \in \{0,1\}^N} \sum_{i: x_i \neq y_i} \omega(x, y) \langle \psi_x^j | P_i | \psi_y^j \rangle. \end{aligned}$$

For every $0 \leq a < N$ and $i \geq 0$, let $\beta_{a,i} = \mathbf{P}_i|\psi_x^j\rangle$, where $x \in \{0, 1\}^N$ is such that $f(x) = a$ ('a' for 'answer'). Then

$$W_j - W_{j+1} = 2 \sum_{0 \leq a < b < N} \sum_{a \leq i < b} \frac{1}{b-a} \beta_{a,i}^* \beta_{b,i},$$

where c^* denotes the complex conjugate of $c \in \mathbb{C}$. Rewrite the above equation in terms of distances $d = b - a$,

$$W_j - W_{j+1} = 2 \sum_{d=1}^{N-1} \sum_{i=0}^{d-1} \frac{1}{d} \left(\sum_{a=0}^{N-d-1} \beta_{a,a+i}^* \beta_{a+d,a+i} \right).$$

For every $0 \leq i < N-1$, let

$$\gamma_i = \left(\sum_{a=0}^{N-1} |\beta_{a,a+i}|^2 \right)^{1/2} \quad \text{and} \quad \delta_i = \left(\sum_{a=0}^{N-1} |\beta_{a,a-i-1}|^2 \right)^{1/2}$$

denote the total mass that queries the oracle at i index-positions above and below the leftmost 1. By the Cauchy–Schwarz inequality,

$$|W_j - W_{j+1}| \leq 2 \sum_{d=1}^{N-1} \sum_{i=0}^{d-1} \frac{1}{d} \gamma_i \delta_{d-i-1}.$$

The right hand side is the written-out product of 3 matrices. Let $\gamma = [\gamma_0, \dots, \gamma_{N-2}]$ and $\delta = [\delta_0, \dots, \delta_{N-2}]^t$, where t denotes transposition, and let M denote the $(N-1) \times (N-1)$ matrix with entry (k, ℓ) defined by

$$(M)_{(k,\ell)} = \begin{cases} \frac{1}{k+\ell+1} & \text{if } k + \ell < N-1 \\ 0 & \text{otherwise} \end{cases}$$

for all $0 \leq k, \ell < N-1$. Then

$$|W_j - W_{j+1}| \leq 2\gamma M \delta \leq 2\|\gamma\|_2 \cdot \|M\|_2 \cdot \|\delta\|_2$$

where $\|K\|_2 = \max\{\|Kv\|_2 : \|v\|_2 = 1\}$ denotes the induced matrix norm.

Since $\|\gamma\|_2^2 + \|\delta\|_2^2 \leq \sum_{a=0}^{N-1} \sum_{i \geq 0} |\beta_{a,i}|^2 \leq N$, we have that $\|\gamma\|_2 \|\delta\|_2 \leq \frac{1}{2}N$. Matrix M is a Hankel matrix, and its norm is upper bounded by the norm of the $(N-1) \times (N-1)$ Hilbert matrix M' defined by $(M')_{(k,\ell)} = \frac{1}{k+\ell+1}$ for all $0 \leq k, \ell < N-1$. The norm of any Hilbert matrix is upper bounded by π (see for example [7] for a neat argument), and hence $|W_j - W_{j+1}| \leq \pi N$. $\square$

5 A $\log_3(N)$ algorithm for ordered search

In this section, we sketch the main elements in our new quantum algorithm for ordered searching. First, we give some general remarks, outline the main parts and discuss the intuition behind the algorithm. We then, in Subsection 5.2, comment on parts of the analysis of its complexity. Our algorithm is exact and requires only $\log_3(N) + O(1)$ queries to the oracle.

Our algorithm bears many resemblances to the classical binary search algorithm. All unitary transformations are “nice” in the sense that the algorithm only uses XOR operations (also referred to as controlled-NOT) and rotations by multiples of angle $\frac{2\pi}{16}$. The requirements to the resolution of the rotations in the algorithm are thus moderate.

In the algorithm, we use a very important idea of *explicitly known bits of the oracle*. If the algorithm can increase the number of explicitly known bits by a factor of F by each query, then we obtain a complexity of $\log_F(N) + O(1)$.

Consider an application of the classical binary search algorithm on an oracle $x \in \{0, 1\}^8$ of length $N = 8$. By definition of the ordered search problem we are promised that $x_8 = 1$ and that $x_i \leq x_{i+1}$ for all $i = 1, \dots, 7$. We say that a bit of the oracle is *explicitly known* if the classical algorithm can output the value of that bit with certainty for all possible input oracles. Initially, only the bit x_8 is explicitly known (since we are promised that $x_8 = 1$). After the first query, the bit x_4 is also explicitly known, and after the second query, the bits $\{x_2, x_4, x_6, x_8\}$ are explicitly known, since independently of which oracle the algorithm is given, it knows the value of these four bits with certainty. Finally, after the third and last query, all 8 bits are explicitly known.

Since it is important for what follows, please do not confuse bits that are *explicitly known* with bits whose value can be deduced only for *some* oracles. As an example, suppose we run the classical binary search algorithm on oracle x for which $x_5 = 0$ and $x_6 = 1$. After the second query, the classical binary search algorithm knows that $x_4 = 0$ and that $x_6 = 1$. From this, it can deduce the values of all 8 bits, but x_5 . However, it is only the values of the four bits $\{x_2, x_4, x_6, x_8\}$ that can be deduced no matter what oracle is given as input, and thus it is only these four bits we consider explicitly known. The concept of explicitly known bits for the classical binary search algorithm is very simple: for an input of length $N = 2^n$, after j queries, there are exactly 2^j bits explicitly known, these being $\{x_{N/2^j}, x_{2N/2^j}, \dots, x_N\}$. The concept of explicitly known bits for our quantum algorithm is almost as simple and it is defined below.

Our quantum algorithm is, in many senses, simply to run many copies of (variations of) the classical binary search algorithm in quantum parallel. Every basis state in every one of the superpositions we ever obtain, has a natural classical interpretation as being the state of a classical computer running some classical search algorithm. Therefore, we shall often refer to basis states of a superposition as *computers*. The point being that every basis state can be thought of as the state of a classical computer in the middle of searching. By making queries in quantum parallel we achieve that some of the computers know more about where in the list the shift from 0's to 1's is. These computers then communicate their knowledge to the rest of the computers in the superposition.

With this, we can define what we mean by explicitly known bits for our quantum algorithm: *We say that a computer in a superposition explicitly knows a bit if it knows the value of that bit regardless of which oracle the algorithm is given as input.* To illustrate what we hereby mean, consider the previous example in which we are given an oracle $x \in \{0, 1\}^8$ of length $N = 8$ with $x_5 = 0$ and $x_6 = 1$.

Suppose that we have superposition of 4 computers. We want to find the shift from 0's to 1's in the oracle. Suppose that 2 of the computers explicitly know 4 bits (the bits 2, 4, 6, and 8), that 1 computer explicitly knows 2 bits (bits 4 and 8) and that 1 computer explicitly knows only 1 bit (bit 8). The following sequence of operations illustrates how

Figure 1: (a) Consider an oracle of size $N = 32$. The graphical representation of how 4 computers each arranges their 11 explicitly known bits of the oracle so that using only 1 query, all 4 computers learn all 32 bits. Each row corresponds to 1 computer, and each small block corresponds to 1 explicitly known bit of the oracle. For instance, the first computer explicitly knows the 11 bits $\{x_8, x_{12}, x_{16}, x_{18}, \dots, x_{32}\}$. Using 4 computers gives 4 symmetrical sublists. Figure (b) illustrates one of these symmetrical sublists.

we, using only a single query, combine the 4 computers so they all know 8 bits.

$$\begin{aligned}
& \begin{array}{c} |0\rangle|1-8\rangle \\ |1\rangle|5-8\rangle \\ \sqrt{2}|1\rangle|5-6\rangle \end{array} \xrightarrow{\mathcal{O}'} \begin{array}{c} |x_4\rangle|1-8\rangle \\ (-1)^{x_6}|1\rangle|5-8\rangle \\ \sqrt{2}(-1)^{x_5}|1\rangle|5-6\rangle \end{array} \xrightarrow{\mathcal{V}^{(8)}} \begin{array}{c} |0\rangle|5-8\rangle \\ (-1)^{x_6}|0\rangle|5-8\rangle \\ \sqrt{2}(-1)^{x_5}|1\rangle|5-6\rangle \end{array} \xrightarrow{\mathcal{U}^{(4)}} \\
& \begin{array}{c} \sqrt{2}|x_6\rangle|5-8\rangle \\ \sqrt{2}(-1)^{x_5}|1\rangle|5-6\rangle \end{array} \xrightarrow{\mathcal{V}^{(4)}} \begin{array}{c} \sqrt{2}|0\rangle|5-6\rangle \\ \sqrt{2}(-1)^{x_5}|1\rangle|5-6\rangle \end{array} \xrightarrow{\mathcal{U}^{(2)}} \begin{array}{c} \sqrt{4}|x_5\rangle|5-6\rangle \\ \sqrt{4}|0\rangle|6-6\rangle \end{array} \xrightarrow{\mathcal{V}^{(2)}} \begin{array}{c} \sqrt{4}|0\rangle|6-6\rangle \\ \sqrt{4}|0\rangle|6-6\rangle \end{array}.
\end{aligned}$$

We have here (without loss of generality) assumed that the query operator $\mathcal{O}'$ is such that all computers but the one that knows the least have their answers given in the phase of their amplitudes. The computer that knows the least is given the answer directly into its leftmost qubit.

To be able to combine the knowledge from several computers we have them distribute their explicitly known bits in a certain way. In Figure 1a it is shown how we for each one of 4 computers distribute 11 explicitly known bits so that after 1 iteration all 4 computers explicitly know 32 bits. The distribution is so that we divide the list into 4 sublists of equal size, where we for each sublist distribute 11 bits as shown in Figure 1b. Similarly, if we have 2^n computers, we divide the list into 2^n sublists of equal size. In general, the more computers we use, the more sublists we have, and the more explicitly known bits each computer needs to have.

5.1 The Algorithm

In each iteration of the algorithm, we utilize 2 operators, $\mathcal{U}^{(s)}$ and $\mathcal{V}^{(s)}$, where $\mathcal{U}^{(s)}$ is used to combine 2 computers and $\mathcal{V}^{(s)}$ makes a computer ready for the next $\mathcal{U}^{(s)}$ operator, which is defined as follows.

$$\mathcal{U}^{(s)} : |b\rangle|\ell-h\rangle \longmapsto \begin{cases} \frac{1}{\sqrt{2}}(|0\rangle + (-1)^b|1\rangle)|\ell-h\rangle & \text{if } s = h - \ell + 1 \\ |b\rangle|\ell-h\rangle & \text{otherwise.} \end{cases} \quad (10)$$

Here b is a single bit, s is a power of 2, and ℓ and h are the endpoints of an interval.

We use the operator defined by Eq. 10 as in the following

$$\alpha|0\rangle|I^{(s)}\rangle + \alpha(-1)^{x^{(\frac{s}{2})}}|1\rangle|I^{(s)}\rangle + \beta|\Phi\rangle \xrightarrow{U^{(s)}} \sqrt{2}\alpha|x^{(\frac{s}{2})}\rangle|I^{(\frac{s}{2})}\rangle + \beta|\Phi\rangle \quad (11)$$

where $I^{(s)}$ is an interval, $x^{(\frac{s}{2})}$ is the bit at the middle of the interval, α and β are real-valued amplitudes satisfying $2\alpha^2 + \beta^2 = 1$, and $|\Phi\rangle$ is a superposition orthogonal to $|0\rangle|I^{(s)}\rangle$ and $|1\rangle|I^{(s)}\rangle$.

The operators $V^{(s)}$ are defined by

$$V^{(s)} : |b\rangle|\ell-h\rangle \mapsto \begin{cases} |0\rangle|\ell-(\ell+\frac{h-\ell+1}{2}-1)\rangle & \text{if } s = h - \ell + 1 \wedge b = 1 \\ |0\rangle|(\ell+\frac{h-\ell+1}{2})-h\rangle & \text{if } s = h - \ell + 1 \wedge b = 0 \\ |b\rangle|\ell-h\rangle & \text{otherwise.} \end{cases} \quad (12)$$

We always use operator $V^{(s)}$ as in the following,

$$|x^{(\frac{s}{2})}\rangle|I^{(s)}\rangle + \beta|\Phi\rangle \xrightarrow{V^{(s)}} |0\rangle|I^{(\frac{s}{2})}\rangle + \beta|\Phi\rangle. \quad (13)$$

Each operator $V^{(s)}$ takes a interval and the value of the bit $x^{(\frac{s}{2})}$ in the middle of that interval, and chooses the upper part of that interval if $x^{(\frac{s}{2})} = 0$, and chooses the lower part if $x^{(\frac{s}{2})} = 1$.

The operators are applied to the state in the following fashion

$$V^{(2)}U^{(2)} \dots U^{(N/2)}V^{(N)}U^{(N)}V^{(2N)}O'. \quad (14)$$

Assume that we have $r = 2^n$ computers which have distributed their explicitly known bits in a way such that we obtain r sublists. The shift from 0s to 1s in the list is in one and only one of these sublists. Consider the sublist containing the shift. First all computers make a query to the oracle in quantum parallel. Then we combine the computers using the 2 operators $U^{(s)}$ and $V^{(s)}$. These operators are applied $\log(r)$ times after a query. After applying this sequence of operations all computers know where in the sublist the shift is. As we have seen $V^{(s)}$ changes the name of the computers so that they can be combined. Operator $U^{(s)}$ combine 2 (sets of) computers.

Suppose that after the application of operator $U^{(s')}$ with, say, $s' = \frac{r}{2^k}$ the state is

$$(\sqrt{2})^k|x^{(\frac{s'}{2})}\rangle|I^{(s')}\rangle + (\sqrt{2})^k(-1)^{x^{(\frac{s'}{4})}}|1\rangle|I^{(\frac{s'}{2})}\rangle + \beta|\Phi\rangle.$$

We now apply the operator $V^{(s')}$ which gives us the state

$$(\sqrt{2})^k|0\rangle|I^{(\frac{s'}{2})}\rangle + (\sqrt{2})^k(-1)^{x^{(\frac{s'}{4})}}|1\rangle|I^{(\frac{s'}{2})}\rangle + \beta|\Phi\rangle,$$

and after the application of operator $U^{(\frac{s'}{2})}$ we have

$$(\sqrt{2})^{k+1}|x^{(\frac{s'}{4})}\rangle|I^{(\frac{s'}{2})}\rangle + \beta|\Phi\rangle.$$

From this we can verify that all computers obtain the explicit knowledge of $2r$ bits (in this sublist) after $\log(r) - 1$ applications of $U^{(s)}$ and $\log(r)$ of $V^{(s)}$. Since the operators $U^{(s)}$ and $V^{(s)}$ are unitary it follows that the operator given by Eq. 14 is unitary.

To be able to apply the iteration again after another query, one must make the above iteration in a superposition so that there now is a superposition of computers that have their explicitly known bits distributed in a structure resembling figure 1. We explain how this is done, including other omitted parts, in the final version of this paper.

5.2 Elements of the analysis

Our routine described above can be utilized to increase to number of known bits by a factor of almost 3 by each iteration. Consider figure 1(a). In this figure, we use 4 computers, one corresponding to each of the 4 rows. Each of the 4 computers knows 11 bits (1+2+4+4) before the iteration, whereas after the iteration, all of them know 32 bits. Thus, using only 1 query, we increase the number of known bits from 11 to 32.

In general, starting with $r = 2^n$ computers, each of them explicitly knows m bits of the oracle, where m is given by

$$m = 1 * 1 + 1 * 2 + 2 * 4 + \dots + \frac{r}{2} * r = 1 + \sum_{k=0}^{n-1} 2^k * 2^{k+1} = \frac{2}{3} 4^n + \frac{1}{3}, \quad (15)$$

after 1 iteration, all of the r computers will know $m' = r * r * 2$ bits. Thus, with just 1 iteration we go from having $m = \frac{1}{3}(2 * 4^n + 1)$ known bits to having $m' = r * r * 2 = 2 * 4^n$ known bits, an expansion factor of almost 3.

Given any value of m we can decompose it into the $\frac{1}{3}(2 * 4^n + 1)$ number system and obtain an expansion factor of almost 3. For integer m , write

$$m = \sum_{k=0}^a \alpha_k * \frac{1}{3}(2 * 4^k + 1),$$

where $\alpha_k \in \{0, 1, 2, 3\}$ for $k = 0, 1, \dots, a$, with $a = \max\{k \mid \alpha_k \neq 0\}$. Using 1 query, we expand m known bits into m' known bits where

$$m' = \sum_{k=0}^a \alpha_k * 2 * 4^k.$$

We achieve an expansion factor of

$$F = \frac{m'}{m} = \frac{\sum_{k=0}^a \alpha_k * 2 * 4^k}{\frac{1}{3} \sum_{k=0}^a \alpha_k * (2 * 4^k + 1)} \geq \frac{3}{1 + \frac{3(a+1)}{2 * 4^a}} = 3 - O\left(\frac{\log(m)}{m}\right). \quad (16)$$

6 Concluding remarks

The inner product of two quantum states is a measure for their distinguishability. For instance, two states can be distinguished with certainty if and only their inner product is 0. In this paper, we have introduced a weighted all-pairs inner product argument as a tool for proving lower bounds in the quantum black box model. We have used this argument to give a better and also simpler lower bound of $\frac{1}{\pi}(\ln(N) - 1)$ for quantum ordered searching. It seems to us that the possibility of using non-uniform weights is particular suitable when proving lower bounds for non-symmetric (possibly partial) functions.

We have chosen here to use inner products which is only one of the many studied measures for distinguishability of states. A striking example of the limitations of using this measure is given by Jozsa and Schlienz in [13]. In [15], Zalka uses a non-linear measure to prove the optimality of Grover's algorithm [12]. Similarly, it might well be that utilizing some other (possibly non-linear) measure of distinguishability could be used to improve our lower bound.

Our algorithm for searching an ordered list with complexity $\log_3(N) + O(1)$ is based on classical binary search combined with communicating knowledge between computers

or basis states. It could be instructive to studying if this view on quantum computation could be useful in constructing quantum algorithms for other problems. Either in the sense if it is possible quantumly to speed up classical algorithms for other problems (where amplitude amplification does not apply) or if it is possible in solutions for other problems to take advantage of communication between computers.
